

Magnetodynamo lifetimes for rocky, Earth-mass exoplanets with contrasting mantle convection regimes

Joost van Summeren,¹ Eric Gaidos,¹ and Clinton P. Conrad¹

Received 12 August 2012; revised 2 April 2013; accepted 5 April 2013; published 16 May 2013.

[1] We used a thermal model of an iron core to calculate magnetodynamo evolution in Earth-mass rocky planets to determine the sensitivity of dynamo lifetime and intensity to planets with different mantle tectonic regimes, surface temperatures, and core properties. The heat flow at the core-mantle boundary (CMB) is derived from numerical models of mantle convection with a viscous/pseudoplastic rheology that captures the phenomenology of plate-like tectonics. Our thermal evolution models predict a long-lived (~ 8 Gyr) field for Earth and similar dynamo evolution for Earth-mass exoplanets with plate tectonics. Both elevated surface temperature and pressure-dependent mantle viscosity reduce the CMB heat flow but produce only slightly longer-lived dynamos (~ 8 – 9.5 Gyr). Single-plate (“stagnant lid”) planets with relatively low CMB heat flow produce long-lived (~ 10.5 Gyr) dynamos. These weaker dynamos can cease for several billions of years and subsequently reactivate due to the additional entropy production associated with inner core growth, a possible explanation for the absence of a magnetic field on present-day Venus. We also show that dynamo operation is sensitive to the initial temperature, size, and solidus of a planet’s core. These dependencies would severely challenge any attempt to distinguish exoplanets with plate tectonics and stagnant lids based on the presence or absence of a magnetic field.

1. Introduction

[2] Many planets in the solar system have or had magnetic fields produced by internal dynamos, and this is presumably also true among planets orbiting other stars. Magnetic fields of exoplanets have yet to be unambiguously detected, but corotating regions of elevated chromospheric emission on the host stars of some close-in giant planets can be explained by magnetic interaction [Shkolnik *et al.*, 2005; Shkolnik *et al.*, 2008; Fares *et al.*, 2012], and one explanation for the inflated radii of many giant planets on close-in orbits is heating by ohmic dissipation during circulation of a partially ionized upper atmosphere through the planet’s magnetic field [Batygin and Stevenson, 2010]. Past or present operation of magnetodynamos has been linked to the interior structure, and thermal evolution of the rocky planets of the inner solar system [Breuer *et al.*, 2010; Stevenson, 2010] and the detection of magnetic fields might, in principle, provide insight into the interiors of exoplanets.

[3] In differentiated silicate-metal planets like the Earth, dynamos are produced by convection within the liquid or partially liquid iron core if the magnetic Reynold’s number $Re_m > 40$ [Stevenson, 2010]. Dynamo operation is associated with ohmic dissipation, which requires entropy production in excess of that from conduction along the core’s adiabat. Entropy production can be due to cooling of the core in excess of conduction, release of latent heat during solidification of an inner core, or formation of buoyant fluid generated by the exclusion of lighter elements such as sulfur when iron crystallizes. All three sources require removal of heat from the core, and thus, core cooling is considered a requirement for dynamo operation. The decay of the long-lived radioactive isotope ^{40}K is another possible energy source [Lee and Jeanloz, 2003; Murthy *et al.*, 2003; Nimmo *et al.*, 2004] although little such potassium may partition into a core [Corgne *et al.*, 2007]. Planetary rotation rate is thought to have little influence on dynamo strength although it may control the relative strength of the dipole and multipolar components [Zuluaga and Cuartas, 2012].

[4] In an Earth-like planet, the core is surrounded by a silicate mantle, and heat must be carried from the core-mantle boundary (CMB) by subsolidus convection. The viscosity of a silicate mantle is strongly temperature-dependent, and most likely, the mantle contains long-lived radionuclides that provide heat and sustain high mantle temperatures over billions of years. The ability of the mantle to carry heat from the core depends also on the style of mantle convection,

distinguished by the degree to which the brittle lithosphere participates in convection, e.g., plate tectonics or stagnant lid modes. Thus, magnetodynamo operation is tied to the tectonics and thermal evolution of the planet’s mantle. The lack of a dynamo in Venus has been ascribed to the apparent absence of plate tectonics [Buffett *et al.*, 1996; Nimmo, 2002].

[5] Previous theoretical studies have predicted the evolution of dynamos in rocky exoplanets [Gaidos *et al.*, 2010; Driscoll and Olson, 2011; Tachinami *et al.*, 2011]. Gaidos *et al.* [2010] examined the effect of surface temperatures and plate tectonics. They found that higher surface temperatures can enhance the dynamo due to the lower viscosity of a hotter mantle and that dynamos are weaker but still operate on planets with stagnant lids. To explain the absence of a present-day dynamo on Venus, it was necessary to invoke an order-of-magnitude enhancement in mantle viscosity. They used parametric models to describe mantle convection and heat transport across the CMB. However, accounting for the complexity of subsolidus convection in a planetary mantle with a strongly temperature-dependent viscosity requires numerical simulations.

[6] Furthermore, numerical models can adequately treat the effects of a nonuniform surface temperature. Rocky planets very close to their parent star will be tidally locked, most likely with a 1:1 spin-orbit ratio, and may lack an atmosphere due to erosion by the stellar wind [Khodachenko *et al.*, 2007]. In this case, temperatures will vary markedly between the irradiated and dark sides, and possible patterns of mantle convection include a degree-one (asymmetric) mode [Van Summeren *et al.*, 2011]. This could enhance heat flow inhomogeneity across the CMB and suppress a dynamo if peak-to-peak variations are of the same order as mean values [Olson and Christensen, 2002].

[7] Finally, the rheology of planetary mantles is expected to be pressure-dependent as well as temperature-dependent, although the pressure-dependence for super-Earths is a topic of controversy. If viscosity increases with pressure [Stamenković *et al.*, 2011], then this will suppress convective vigor in the deep mantles of massive planets [Wagner *et al.*, 2011] (P. J. Tackley *et al.*, Mantle dynamics in super-Earths: Post-perovskite rheology and self-regulation of viscosity, submitted to *Icarus*, 2013, hereinafter referred to as Tackley *et al.*, submitted manuscript, 2013), which in turn will reduce heat flow across the CMB. Tachinami *et al.* [2011] predict that, above a critical planetary mass, enhanced viscosity terminates dynamo operation. On the other hand, Karato [2011] argues for a decrease in viscosity with pressure by 2 to 3 orders of magnitude due to changes in the diffusion mechanism (from vacancy to interstitial) and a series of chemical and electronic phase transitions over 0.1–1 TPa. If this is correct, then the deep mantles of super-Earths will be less viscous, and layered convection may occur.

[8] To more thoroughly investigate the conditions for the appearance of dynamos in Earth-like exoplanets, we investigated the influence of differences in convective regime, surface temperature, pressure-dependence of mantle viscosity, and a range of core properties (radius, temperature, thermal conductivity, and solidus) on the lifetimes and intensities of magnetodynamos in planets with the same mass and interior structure as Earth. We show how dynamos can be

longer-lived for planets with immobile surfaces compared to those with plate tectonics. We then determined the sensitivity of dynamo behavior to the planetary and physical parameters of our simulations and assessed how informative dynamo-generated fields may be for probing the interior dynamics of exoplanets.

2. Methods

2.1. General Modeling Approach

[9] To explore parameter space, we calculated a series of dynamo evolution calculations for different mantle tectonic regimes, surface temperatures, and core properties. A corresponding number of forward calculations for mantle evolution over billions of years is computationally impractical. Therefore, we adopted the following approach: (1) We calculated the steady state CMB heat flow, $\overline{Q}_{\text{CMB}}$, from numerical models of mantle convection with an imposed constant CMB temperature, T_{CMB} , and rate of mantle internal heating, H_m . (2) We repeated this procedure for different CMB temperatures to derive parameterizations of $\overline{Q}_{\text{CMB}}$ versus T_{CMB} for each convection scenario. (3) We employed these parameterizations in an analytical model for the thermal evolution of an iron core, which we solved numerically. In these models, we rescaled the $\overline{Q}_{\text{CMB}}$ values to account for time-dependent mantle internal heating rates, consistent with boundary layer theory. (4) We calculated dynamo intensities using a scaling law with core entropy terms.

2.2. Thermal Model of the Core

[10] We consider liquid/solid Fe cores with the same total radius of that of Earth, except in section 3.4 where we vary the core radius. To estimate the intensity of a magnetic dipole field at the CMB (B_{CMB}), we adopt the following scaling law derived from numerical dynamo simulations [Christensen and Aubert, 2006; Olson and Christensen, 2006; Aubert *et al.*, 2009]:

$$B_{\text{CMB}} = \alpha \sqrt{\mu_0 \bar{\rho}} \left[\frac{\Phi \bar{T}}{M_c} (r_{\text{CMB}} - r_i) \right]^{1/3}, \quad (1)$$

with Φ denotes the entropy production rate associated with ohmic dissipation due to electrically charged currents in a conducting fluid, μ_0 denotes the magnetic diffusivity, $\bar{\rho}$ denotes the average core density, \bar{T} denotes the temperature at which ohmic dissipation occurs [Roberts *et al.*, 2003], M_c denotes the core mass, and r_{CMB} and r_i denote the radii of the CMB and inner-outer core boundary, respectively. Parameters and values are listed in Table 1. The dimensionless coefficient $\alpha = c_1 \cdot b_{\text{dip}} = 0.165$ combines a prefactor used to extrapolate dynamo modeling results from comparatively small Rayleigh numbers and large Ekman and magnetic Prandtl numbers to planetary conditions ($c_1=1.65$) [Aubert *et al.*, 2009] and a fitting coefficient that relates the mean field strength inside the core to the dipole field at the CMB ($b_{\text{dip}} \approx 10$) [Aubert *et al.*, 2009]. The adopted scaling law successfully predicts the magnetic moments of the solar system planets and Ganymede [Olson and Christensen, 2006]. For pure dipoles, the average field intensities at the planetary surface and CMB are related through $B_{\text{srfc}} \approx (r_{\text{CMB}}/r_{\text{srfc}})^3 B_{\text{CMB}}$.

Table 1. Planetary Core Parameters and Values Used in This Study^a

Quantity	Symbol	Value	Unit
B	Magnetic field strength		T
c_{P_c}	Core specific heat	*850 ^(a)	J kg ⁻¹ K ⁻¹
$D_{\text{cen}} = \sqrt{\frac{3c_p}{2\pi\alpha\rho_{\text{cen}}G}}$	Thermal length scale	*6.17×10 ⁶	-
$f = \frac{r_i}{r_{\text{CMB}}}$	Ratio inner-to-outer core radius		-
G	Gravitational constant	6.67 × 10 ⁻¹¹	m ³ kg ⁻¹ s ⁻²
k_c	Heat conductivity core	120 ^(b)	W m ⁻¹ K ⁻¹
K_0	Incompressibility at zero pressure	110 ^(c)	GPa
$L = \sqrt{\frac{9K_0}{2\pi G\rho_0\rho_{\text{cen}}} \left(\ln\left(\frac{\rho_{\text{cen}}}{\rho_0}\right) + 1 \right)}$	Density length scale	*6.55×10 ⁶	-
M_c	Core mass	*1.8×10 ²⁴	kg
r_i	Inner core radius		m
r_{CMB}	CMB radius	*3.48×10 ⁶ ^(d)	m
$T_{\text{sol}}^{\text{cen}}$	Solidus temperature Fe at center	5391	K
T	Effective dissipation temperature	3500	K
ΔS	Entropy of fusion	118 ^(e)	J mol ⁻¹ K ⁻¹
α_{cen}	Thermal expansivity at center	*1.3×10 ⁻⁵ ^(f)	K ⁻¹
$\bar{\rho}$	Average core density		kg m ⁻³
$\Delta\rho$	Density jump at inner-outer core boundary	400 ^(g)	kg m ⁻³
ρ_0	Iron density at zero pressure	7019 ^(c)	kg m ⁻³
γ	Grüneisen parameter	*1.2	-
$\lambda = 1/(\mu_0\sigma)$	Magnetic diffusivity	2	m ² s ⁻¹
μ_0	Permeability of free space	4 π × 10 ⁻⁷	N A ⁻²
Φ	Entropy production rate associated with ohmic dissipation		W K ⁻¹

^aSubscript conventions are “0” for zero pressure, “srfc” for surface, “m” for mantle, “c” for core, “cen” for planetary center, “CMB” for core-mantle boundary, and “i” for inner core. Values annotated with an asterisk (*) are specific for the nominal-like Earth model C (Table 3). Values are from (a) *Wang et al.* [2002], (b) *De Koker et al.* [2012]; *Pozzo et al.* [2012], (c) *Anderson and Ahrens* [1994], (d) *Dziewonski and Anderson* [1981], (e) *Poirier and Shankland* [1993], (f) *Dziewonski and Anderson* [1981]; *Labrosse* [2003], and (g) *Buffet et al.* [1996].

[11] We calculated the entropy production rate associated with ohmic dissipation, Φ , from the time-dependent entropy balance for the core as follows:

$$\Phi + E_K = E_S + E_L + E_G. \quad (2)$$

[12] The right-hand side of equation (2) contains the source terms associated with secular cooling (E_S), release of latent heat (E_L), and release of gravitational potential energy (E_G). The sink term E_K is the entropy associated with maintaining thermal conduction along an adiabatic temperature gradient. A convection-driven dynamo requires $\Phi > 0$. Expressions for the terms of equation (2) are listed in Table 2 and are based on *Nimmo* [2009] and *Gaidos et al.* [2010] and references therein.

[13] For a vigorously convecting core, one can assume a hydrostatic, isentropic, and well-mixed state. The associated adiabatic density and temperature profiles can be approximated as follows [*Labrosse et al.*, 2001; *Labrosse*, 2003; *Nimmo*, 2007]:

$$\rho(r) = \rho_{\text{CMB}} \exp\left[\frac{r_{\text{CMB}}^2 - r^2}{L^2}\right] \quad (3)$$

and

$$T_{ad}(r) = T_{\text{CMB}} \exp\left(\frac{r_{\text{CMB}}^2(t) - r^2}{D^2}\right), \quad (4)$$

where ρ_{CMB} and T_{CMB} are the CMB density and temperature, respectively, and L and D are the density and thermal

length scales, respectively (Table 1). The assumed thermal equilibration between inner and outer core is reasonable if the timescale of inner core convection is shorter than that of

Table 2. Terms of the Energy (Q) and Entropy (E) Balance (Section 2.2)^a

Energy	
$Q_S^{(a)}$	$M_c c_{P_c} \left[1 + \frac{2}{5} \left(\frac{r_{\text{CMB}}}{D_{\text{cen}}}\right)^2 + \frac{4}{35} \left(\frac{r_{\text{CMB}}}{D_{\text{cen}}}\right)^4 + \frac{12}{175} \left(\frac{r_{\text{CMB}}}{D_{\text{cen}}L}\right)^2 \right] \frac{dT_{\text{CMB}}}{dt}$
$Q_L^{(a)}$	$\frac{-3M_c \Delta S f}{2(\Delta-1)} \left(\frac{D_{\text{cen}}}{r_{\text{CMB}}}\right)^2 \exp\left(\frac{r_{\text{CMB}}^2 - r_{\text{ic}}^2}{D_{\text{cen}}^2}\right) \frac{dT_{\text{CMB}}}{dt}$
$Q_G^{(b)}$	$\frac{-3\pi G \bar{\rho} M_c F D_{\text{cen}}^2}{T_{\text{CMB}}} \frac{\Delta \rho}{\rho(\Delta-1)} \frac{dT_{\text{CMB}}}{dt}$

$E_S^{(a)}$	$\frac{-2M_c c_{P_c}}{5T_{\text{CMB}}} \left(\frac{r_{\text{CMB}}}{D_{\text{cen}}}\right)^2 \left[1 + \frac{2}{7} \left(\frac{r_{\text{CMB}}}{D_{\text{cen}}}\right)^2 + \frac{6}{35} \left(\frac{r_{\text{CMB}}}{L}\right)^2 \right] \frac{dT_{\text{CMB}}}{dt}$
$E_L^{(a)}$	$\frac{-3M_c \Delta S}{2T_{\text{CMB}}(\Delta-1)} \frac{\rho_{\text{ic}}}{\bar{\rho}} f(1-f^2) \left[1 + \left(\frac{r_{\text{CMB}}}{D_{\text{cen}}}\right)^2 \frac{1-f^2}{2} \right] \frac{dT_{\text{CMB}}}{dt}$
$E_G^{(b)}$	$\frac{Q_G}{T_{\text{CMB}}}$
$E_K^{(b)}$	$\frac{12M_c k_c r_{\text{CMB}}^2}{5\bar{\rho} D_{\text{cen}}^2} (1-f^5)$

^aSubscripts S, L, G, and K refer to secular cooling, latent heat release, gravitational energy release, and conductive cooling, respectively. Other symbols are given in Table 1. The quantity F in the gravitational terms is $\left(\frac{1}{5} + \frac{2}{15}f^5 - \frac{f^2}{3}\right) \frac{f}{1-f^3}$, with $f = r_i/r_{\text{CMB}}$ denotes the ratio of inner to outer core radius. Expressions are from (a) *Gaidos et al.* [2010] and (b) *Nimmo* [2009] and references therein.

Figure 1. Convective flow field (arrows) and potential temperature (colors) at a model time of $t = 4.4$ Gyr in a 2-D, annular model of mantle convection for a nominal Earth-like scenario (C in Table 3). Dimensionless values of the mantle potential temperatures correspond to a range of 273–2673 K.

inner core growth [Labrosse *et al.*, 2001], a likely condition during the early stages of inner core growth [Buffett, 2009].

[14] We calculated core solidification by expressing the solidus (T_{sol}) as a Lindemann law of melting [e.g., Labrosse *et al.*, 2001]

$$\frac{\partial \log T_{\text{sol}}}{\partial \log \rho} = -2 \left(\gamma - \frac{1}{3} \right), \quad (5)$$

where γ is the Grüneisen parameter. We ignored the possible effect of unknown concentrations of light elements such as sulfur on the phase diagram of the core. In all our calculations, the core solidifies from the planetary center outward. Solidification at the top of the core (iron snow) is more likely for planets of two Earth masses or more [Gaidos *et al.*, 2010].

[15] We used the following energy balance equation for the core:

$$Q_{\text{CMB}} = Q_S + Q_L + Q_G. \quad (6)$$

The source terms are the secular core cooling Q_S , the latent heat release Q_L , and the gravitational energy release Q_G (specified in Table 2). The CMB heat flow Q_{CMB} is the only relevant sink term and implicitly includes conductive heat transport in the core along an adiabat. We neglected core heating from the decay of radioactive isotopes such as ^{40}K , as well as viscous dissipation [Braginsky and Roberts, 1995]. Because Q_S , Q_L , and Q_G all depend linearly on the cooling rate dT_{CMB}/dt (Table 2), this cooling rate is readily solved if the heat flow Q_{CMB} is known. We use dT_{CMB}/dt to solve the entropy terms (equation (2) and Table 2) and to update the core temperature profile (equation (4)) and inner core radius at model time steps of 1 Myr.

[16] We characterized magnetodynamo evolution by (1) the onset time of inner solid core formation, t_{ons} , when Q_L and Q_G become nonzero and the dynamo intensifies, (2) the

dynamo cessation time, t_{mag} , defined as the time at which the dipole field intensity reduces to zero due to core freeze-out, and (3) the maximum dipole field intensity from the start of the model until core solidification is complete, $B_{\text{CMB}}^{\text{max}}$. We neglected the possibility that part of the liquid core would not contribute to the magnetodynamo due to stable thermal and/or chemical stratification. However, we identified epochs of partial stabilization by calculating the onset times of thermal stratification, t_{strat} , i.e., when $Q_{\text{CMB}} < Q_K$ with Q_K denotes the thermal conduction along the adiabatic temperature gradient at the top of the core (Table 2). For Earth, a stratified layer is probably $\lesssim 100$ km thick [Gubbins, 2007], and its influence on the magnetodynamo is likely small.

2.3. Dynamical Model of the Mantle

[17] We calculated $\overline{Q_{\text{CMB}}}$ values from numerical models of mantle convection with constant internal heat production (4×10^{-12} W kg $^{-1}$). The methodology of our mantle convection models has been described in detail in Van Summeren *et al.* [2011], and here, we discuss only the aspects relevant for this paper. Mantle flow was described by a Boussinesq formulation of an incompressible fluid at infinite Prandtl number. The associated conservation equations for mass, momentum, and energy were solved using the finite element package CitComS-3.1.1 [Zhong *et al.*, 2000]. The mantle domain is modeled as a 360° annulus (Figure 1), with 513×65 mesh nodes in the lateral and vertical direction, respectively, and mesh refinement toward the top and bottom boundaries where the largest viscosity contrasts occur.

[18] To permit plate-like behavior of the surface boundary layer, we used a composite viscous/pseudoplastic rheology model [Tackley, 2000]. In low-stress regions, we assigned an Arrhenius-type rheology as follows:

$$\eta_v(T'_p) = \eta_0 \exp \left[23.03 \left(\frac{1}{1+T'_p} - \frac{1}{2} \right) \right], \quad (7)$$

with reference viscosity $\eta_0 = 5 \times 10^{20}$ Pa s. The dimensionless potential temperature T'_p scales to the dimensional potential temperature T_p as $T'_p = (T_p - 273)/2400$. The viscosity η_v decreases by 5 orders of magnitude when T_p increases from 273 to 2673 K. In regions where the convective stress exceeds an assigned yield stress (σ_y), we implemented pseudoplastic yielding by recalculating of the viscosity $\eta_y = \sigma_y / 2\epsilon_{II}$, where ϵ_{II} is the second invariant of the strain rate tensor. This yielding allows for lithospheric breakup and concentrates strain in narrow regions. We computed the composite mantle viscosity as $\eta_m = \min(\eta_v(T'_p), \eta_y)$. We assigned $\sigma_y = 150$ MPa in our convection experiments, except for the stagnant lid case where pseudoplastic yielding is precluded. This parameterization underestimates the temperature dependence of viscosity compared to experimental flow laws for olivine [e.g., Hirth and Kohlstedt, 2003], but it avoids sharp viscosity gradients that are computationally expensive. This viscosity parameterization is commonly used in modeling the dynamics of planetary mantles and successfully reproduces the phenomenology of plate-like tectonics by localizing strain in regions that resemble subduction zones and spreading ridges [Tackley, 2000; Van Heck and Tackley, 2008; Foley and Becker, 2009; Van Summeren *et al.*, 2011]. Although the viscous strength of plates is underestimated, plate tectonics is successfully reproduced

Figure 2. Statistically steady state surface heat flow for models with (time-independent) mantle internal heating $H_m = 2, 4,$ and $6 \times 10^{-12} \text{ W kg}^{-1}$ (circle, diamond, and triangle, respectively). The model with $H_m = 4 \times 10^{-12} \text{ W kg}^{-1}$ (diamond) is reference scenario C (Figure 1 and Table 3). The solid line shows the theoretical trend from boundary layer theory for internally heated systems ($Q_{srfc} = H_m^{0.25}$).

because surface deformation occurs by yielding rather than viscous deformation.

[19] For each scenario, we computed eight cases with CMB potential temperatures in the range $T_{\text{CMB}_p} = 1873\text{--}3473 \text{ K}$ ($T_{\text{CMB}_p} = 0.67\text{--}1.33$). We calculated physical (or “real”) CMB temperatures (T_{CMB}) from potential temperatures (T_{CMB_p}) by correcting for the influence of adiabatic compressibility: i.e., using $T_{\text{CMB}} = T_{\text{CMB}_p} \exp(Di)$, with dissipation number $Di = \alpha_m g h / c_{P_m} = 0.46$, mantle thermal expansivity $\alpha_m = 2 \times 10^{-5} \text{ K}^{-1}$, mantle gravitational acceleration $g = 10 \text{ m s}^{-2}$, mantle thickness $h = 2.891 \times 10^6 \text{ m}$, and mantle heat expansivity $c_{P_m} = 1250 \text{ J kg}^{-1} \text{ K}^{-1}$. Because each model has a constant CMB temperature and heat production, Q_{CMB} eventually reaches a statistically steady state value, Q_{CMB} . Typically, we ran each case for a model time of $\sim 9 \text{ Gyr}$ (i.e., 32,000 model time steps), and we removed the first $\sim 5 \text{ Gyr}$ (12,000 time steps) to exclude initial transients. For the results presented in section 3.4, we increased the maximum core temperature to $T_{\text{CMB}}^{\text{init}} = 5500 \text{ K}$ by extrapolating the heat flow data, using linear regression to the filled symbols shown in Figure 3b. We applied the same technique to estimate Q_{CMB} for $T_{\text{CMB}} > 5000 \text{ K}$ for scenario VI (i.e., the case represented by the right-hand brown circle in Figure 3a relies on extrapolation).

[20] To account for a time-dependent rate of mantle internal heat production, we rescaled the CMB heat flow using the quasi steady state condition $Q_{\text{CMB}}(t) = Q_{srfc}(t) - H_m(t)$. We scaled the surface heat flow by $Q_{srfc}(t) \propto Ra_H^\beta(t)$, with $Ra_H(t) = \alpha_m \rho_m^2 g H_m(t) h^3 / k_m \kappa_m \eta_m$ is the Rayleigh number for an internally heated fluid, $k_m = 5.65 \text{ W}^{-1} \text{ K}^{-1}$ is the mantle thermal conductivity, and $\rho_m = 4500 \text{ kg m}^{-3}$ is the mantle reference density. We thus have $Q_{srfc}(t) \propto H_m^\beta(t)$. We also assumed a quasi steady state heat balance for the unscaled terms (indicated with subscripts “0”): $Q_{srfc_0} = Q_{\text{CMB}_0} + H_{m_0}$. We then rescaled the CMB heat flow with

$$Q_{\text{CMB}}(t) = (Q_{\text{CMB}_0} + H_{m_0}) \left[\frac{H_m(t)}{H_{m_0}} \right]^\beta - H_m(t). \quad (8)$$

We used $\beta = 0.25$, consistent with boundary layer theory for an internally heated mantle. Deviations from the theory may arise, for example, due to contributions from bottom heating or the dependence of Ra_H on mantle heating rate through η_m . We validated that $\beta = 0.25$ is appropriate for our models by calculating the surface heat flow from two verification experiments with mantle internal heating rates 2×10^{-12} and $6 \times 10^{-12} \text{ W kg}^{-1}$ (Figure 2), which yielded $\beta = 0.27$. We evolved the mantle heat production rate with respect to time as follows:

$$H_m(t) = \sum_i C^i H^i \exp \left[\frac{-t \ln 2}{\tau_{1/2}^i} \right], \quad (9)$$

with isotope concentration C , heat production rate H , and half-life time $\tau_{1/2}$, for radiogenic isotopes ^{238}U , ^{235}U , ^{232}Th , and ^{40}K (values from *Turcotte and Schubert* [2002], Table 4-2). Estimates for present-day mantle heating (e.g., $7.4 \times 10^{-12} \text{ W kg}^{-1}$) [*Turcotte and Schubert*, 2002] depend on assumptions of the Urey number. To account for this uncertainty, we considered a range of H_{m_0} values (1×10^{-12} – $8 \times 10^{-12} \text{ W kg}^{-1}$) and adjusted the heat production rates for radiogenic isotopes H^i (equation (9)), accordingly.

[21] For comparison with boundary layer theory, we recast our results in terms of dimensionless parameters and express Q_{CMB} as

$$Q_{\text{CMB}} = 4\pi r_{\text{CMB}} k_m (T_{\text{CMB}_p} - < T_{m_p} >) Nu_{\text{CMB}}, \quad (10)$$

with Nu_{CMB} denotes the Nusselt number for the bottom boundary layer. Boundary layer theory predicts $Nu_{\text{CMB}} \propto Ra_{\text{CMB}}^{1/3}$ for a bottom-heated mantle [*Schubert et al.*, 2001]. We define the Rayleigh number for the bottom boundary layer as

$$Ra_{\text{CMB}} = \frac{\rho_m g \alpha_m (T_{\text{CMB}_p} - < T_{m_p} >) h^3}{\kappa_m < \eta_m >}. \quad (11)$$

2.4. Parameter Values and Model Scenarios

[22] We calculated CMB heat flows for five scenarios of mantle convection and temperature (Table 3). We simulated a nominal Earth (“cold” or C model) with a uniform surface temperature $T_{srfc} = 273 \text{ K}$. Using a “hot” (H) model with a uniform $T_{srfc} = 759 \text{ K}$, we simulated a close-in planet ($a = 0.13 \text{ AU}$) with efficient surface heat redistribution. An “asymmetric” (A) model was used for close-in planets ($a = 0.13 \text{ AU}$) that lack heat redistribution, and we assigned a surface temperature that is elevated at the substellar point ($T_{srfc} = 1073 \text{ K}$), decreases gradually to the terminus, and is constant on the nightside ($T_{srfc} = 273 \text{ K}$). To investigate planets with an immobile surface and convecting interior, such as Venus, we ran a “stagnant lid” (SL) model by removing pseudoplastic behavior from the viscosity parameterization. For the “viscosity increase” (VI) model, we assigned an exponential increase of the viscosity by a factor of 10 across the mantle depth range, in addition to temperature-dependent viscosity (equation (7)).

[23] We complemented our investigation of different convection regimes (sections 3.1–3.3) with a study of the sensitivity of results to core properties (section 3.4). We calculated the sensitivity of the dynamo cessation time (t_{mag}) and maximum CMB field intensity ($B_{\text{CMB}}^{\text{max}}$) to two planetary

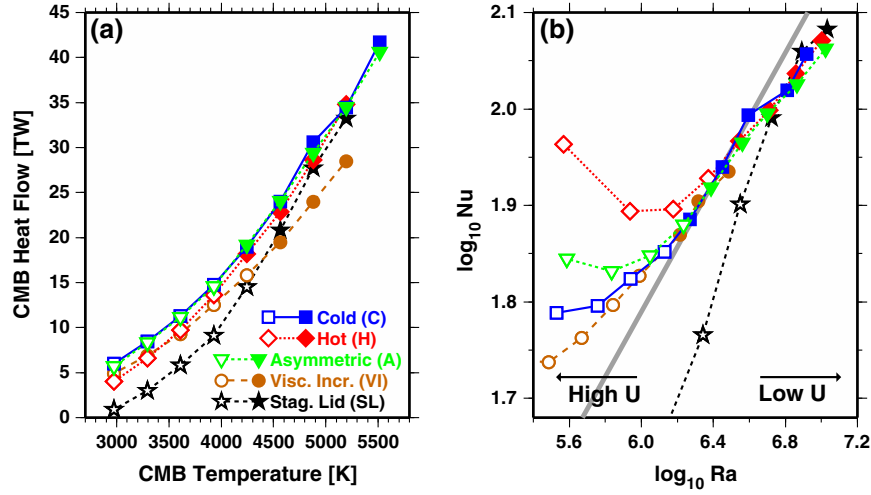

Figure 3. (a) Statistically steady state CMB heat flow, \overline{Q}_{CMB} , as a function of the CMB temperature, T_{CMB} . Results are for mantle convection scenarios C (cold surface), H (hot surface), A (surface with asymmetric temperature), SL (stagnant lid), and VI (depth-increasing viscosity) (Table 3). Filled symbols indicate cases where bottom heating dominates over internal heat production in the mantle ($U < 0.5$) (b) Heat flow curves recast in terms of dimensionless parameters Nu_{CMB} (equation (10)) and Ra_{CMB} (equation (11)). The grey line depicts the power-law relationship $Nu_{CMB} \propto Ra^{1/3}$ predicted from boundary layer theory.

properties: core radius (r_{CMB}) and initial CMB temperatures (T_{CMB}^{init}), all for the nominal C scenario of mantle tectonics. We also calculated the sensitivity of our results to core solidus (T_{sol}) and heat conductivity (k_c), parameters for which the values at pressures corresponding to Earth’s center are controversial [Morard *et al.*, 2011]. Our solidus range equates to a range of the Grüneisen parameter $\gamma \in [1.1-1.4]$, reflecting current uncertainties in high-pressure mineral physics. Where we varied r_{CMB} , we recalculated the interior structure using the interior model described in Gaidos *et al.* [2010]. This uses the third-order Birch-Murnaghan (BM) equations of state and includes the Thomas-Fermi-Dirac contribution to the pressure using the formulation of Zapolsky and Salpeter [1969]. The density in the liquid part of the core is adjusted by a fixed fraction $\delta\rho/\rho$ to account for the presence of light elements [Lee and Jeanloz, 2003]. We adjusted the solidus at the planetary center according to equation (5). For a valid comparison, we adjusted the mantle thickness to maintain a constant Rayleigh number, i.e., the

product of mantle density, gravitational acceleration, and the cube of the mantle thickness, evaluated at the CMB.

3. Results

3.1. Mantle Dynamics and CMB Heat Flow

[24] Figure 3a shows our computed CMB heat flow \overline{Q}_{CMB} as a function of T_{CMB} for the five mantle convection scenarios described in section 2.3 and listed in Table 3. Models C, H, and A build on the work of Van Summeren *et al.* [2011], and their dynamics will be discussed only briefly. The nominal Earth-like scenario C with a cold surface ($T_{surf} = 273$ K) is characterized by plate-like behavior with rigid lithospheric plates that are broken by narrow regions of high strain that resemble slab-like downwellings and ridge-like upwellings (Figure 1). The \overline{Q}_{CMB} values increase with increasing T_{CMB} (Figure 3a, blue curve), which reflects elevated heat transport in a more vigorously convecting mantle.

Table 3. Specification for the Five Mantle Convection Models C, H, A, SL, and VI (Section 2.4)^a

Model Name	Abbrev.	T_{surf} (K)	σ_y (MPa)	t_{ons} (Gyr)	t_{mag} (Gyr)	t_{strat} (Gyr)	B_{CMB}^{max} (μT)
Cold	C	273	150	4.1	8.2	NA	310
Hot	H	1073	150	4.4	8.7	8.4	310
Asymmetric	A	273–1073	150	4.2	8.2	NA	309
Depth-increasing viscosity	VI	273	150	5.0	9.3	9.0	300
Stagnant lid	SL	273	NA	5.0	10.6	4.4	261

^aSurface temperatures T_{surf} are uniform across the planet, except for model A, where the surface temperature is 1073 K at the substellar point, decreases sinusoidally toward the terminus, and is kept constant on the nightside at 273 K. For model SL, pseudoplastic rheology is excluded (σ_y does not apply). Model VI differs from model C by having an exponential viscosity increase of a factor of 10 across the mantle depth range, in addition to temperature-dependent viscosity. Magnetodynamo diagnostics are onset time of inner core formation (t_{ons}), time of dynamo cessation due to core freeze-out (t_{mag}), onset time of thermal stratification (t_{strat} , only applies if $t_{strat} < t_{mag}$), and the maximum intensity of the dipole field at the CMB (B_{CMB}^{max}). NA, not applicable.

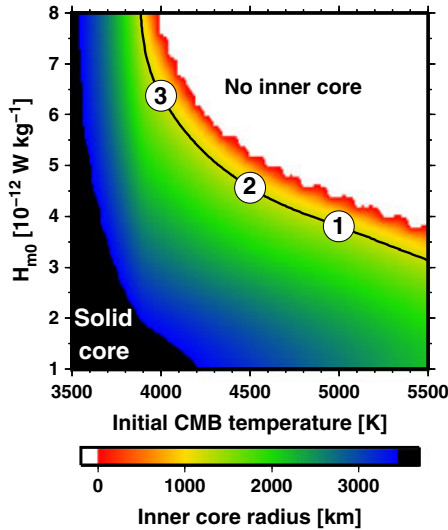

Figure 4. Calculated inner core radius after a model time of $t = 4.5$ Gyr as a function of initial CMB temperature ($T_{\text{CMB}}^{\text{init}}$) and present-day radiogenic mantle heat production rate (H_{m_0}). The black contour marks Earth’s present-day inner core radius of 1220 km. Labels indicate three scenarios that reproduce a 1220 km inner core at $t = 4.5$ Gyr by using respective values of H_{m_0} and $T_{\text{CMB}}^{\text{init}}$: (1) $3.8 \times 10^{-12} \text{ W kg}^{-1}$, 5000 K; (2) $4.6 \times 10^{-12} \text{ W kg}^{-1}$, 4500 K; (3) $6.4 \times 10^{-12} \text{ W kg}^{-1}$, 4000 K. Corresponding dynamo evolutions for these cases are shown in Figure 5d.

[25] In scenario H of a close-in planet with a uniformly elevated surface temperature ($T_{\text{surf}} = 759 \text{ K}$), the surface boundary is too weak to maintain coherent plates. Instead, the surface material is highly mobile and deforms diffusely, a possibility for close-in planets with surface temperatures close to the silicate solidus. We limited the temperature dependence of viscosity for numerical reasons and therefore likely underestimated the viscosity of the surface boundary layer. Planets with $T_{\text{surf}} = 759 \text{ K}$ may instead have immobile or episodically overturning surfaces [Armstrong and Tackley, 2012], and we investigated this stagnant lid behavior with our SL models, described below. For scenario H, the $\overline{Q}_{\text{CMB}}$ values are only slightly smaller than for scenario C (Figure 3a, cf. red and blue curves). Indeed, the elevated surface temperature causes a mantle temperature increase that reduces the CMB heat flow, but this is mostly offset by a lower viscosity in the hot boundary layer that enhances CMB heat flow.

[26] In scenario A, the hemispheric contrast in surface temperatures causes a tectonic dichotomy with diffuse deformation on the hot dayside (similar to scenario H) and plate-like tectonics on the cold nightside (similar to scenario C) [Van Summeren et al., 2011]. This mixed style of surface deformation results in $\overline{Q}_{\text{CMB}}$ values that are intermediate those of scenarios C and H (Figure 3a). An asymmetric (harmonic degree 1) convection pattern develops in the mantle interior. This pattern involves convective upwellings that are concentrated near the hot substellar point, near-surface flow from the hot dayside to the cold nightside where downwellings

concentrate, and a deep mantle return flow toward the dayside. A small hemispheric heterogeneity in CMB heat flow of $\sim 10\%$ in scenario A is unlikely to destabilize a dynamo [Olson and Christensen, 2002].

[27] In scenario VI (in which viscosity increases with pressure), CMB heat flows are $\sim 15\text{--}25\%$ lower than in scenario C (Figure 3a). This reflects the depth-increasing viscosity which suppresses deep mantle convective overturn and hinders descending cold slabs from covering and cooling the core. As a result, a thicker, less conducting CMB boundary layer develops, relative to reference scenario C.

[28] The stagnant lid convection scenario SL has an immobile surface through which heat is conducted, but vigorous convection still occurs in the underlying mantle. The $\overline{Q}_{\text{CMB}}$ values are lower than for models C, H, and A for the T_{CMB} range we investigated (Figure 3b). This is because slow heat transport through the immobile surface reduces the temperature difference between the mantle interior and the core.

[29] We expressed our results in dimensionless quantities, i.e., the Nusselt and Rayleigh numbers of the bottom boundary layer as defined by equations (10) and (11). When bottom heating dominates (i.e., for Urey number $U < 0.5$), our results approach the theoretical one-third power-law relationship for a bottom-heated mantle [Schubert et al., 2001] (Figure 3b). Calculated Nu_{CMB} values deviate from the theoretical value when internal heating dominates ($U > 0.5$), which occurs for $T_{\text{CMB}} \lesssim 4000\text{--}4500 \text{ K}$ in our models (Figure 3b). For $U > 0.5$, Nu_{CMB} is larger for scenarios H and A than for scenario C (Figure 3b) because (locally) elevated surface temperatures thermally buffer the mantle interior and reduce the temperature contrast with the core (equation (10)). The CMB heat flow also decreases, but this is mostly compensated by more efficient heat transport resulting from decreased mantle viscosity. Compared to scenario C, scenarios VI and SL have a lower Nu_{CMB} which reflects a lower CMB heat flow due to the weaker influence of cold slabs in the deep mantle.

3.2. Nominal Thermal Evolution of the Core

[30] We calibrated the nominal Earth-like scenario by reproducing Earth’s present-day inner core radius of 1220 km and heat flow of 5–15 TW [Lay et al., 2008] at a model time of 4.5 Gyr. In calculating the thermal evolution of the core, we accounted for time-dependent mantle heating by rescaling the parameterized CMB heat flow values (Figure 3, blue curve) and investigated the range of $T_{\text{CMB}}^{\text{init}}$ and H_{m_0} values shown in Figure 4. Different combinations of parameter values can reproduce Earth’s inner core radius. For example, the calculated present-day inner core radius increases for progressively lower $T_{\text{CMB}}^{\text{init}}$, lower H_{m_0} , or higher solidus T_{sol} (i.e., larger Grüneisen parameter γ) and the present-day $\overline{Q}_{\text{CMB}}$ increases for higher $T_{\text{CMB}}^{\text{init}}$, lower H_{m_0} , or higher T_{sol} . We chose $T_{\text{CMB}}^{\text{init}} = 5000 \text{ K}$, $H_{m_0} = 3.8 \times 10^{-12} \text{ W kg}^{-1}$ (label 1 in Figure 4), and $\gamma = 1.3$ ($T_{\text{sol}}^{\text{cen}} = 5391 \text{ K}$) and the corresponding core evolution (Figures 5a–5c) serves as a reference for other scenarios. Dynamo operation starts at $t \sim 0.8 \text{ Gyr}$ ($\Phi > 0$, Figure 5c), when the CMB heat flow has become sufficiently large ($\sim 14 \text{ TW}$) after an initial period of strong mantle heating that suppresses the CMB heat flow (Figure 5b). After inner core formation ($\sim 4.1 \text{ Gyr}$), latent heat and gravitational

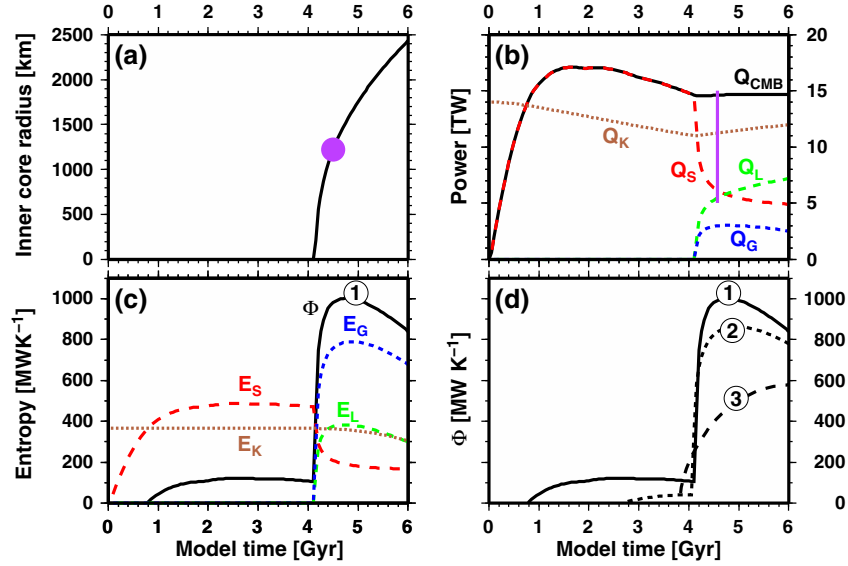

Figure 5. Thermal evolution of the core for nominal Earth-like scenario C. (a) Inner core radius. The purple circle shows Earth’s present-day value. (b) Energy and (c) entropy terms (equations (2) and (6) and Table 2). Label subscripts K, L, S, and G are for conduction, latent heat, secular cooling, and gravitational energy release, respectively. Q_{CMB} is the CMB heat flow, and Φ is the entropy production rate associated with ohmic dissipation. The initial CMB temperature used in this model is $T_{CMB}^{init}=5000$ K, and the present-day mantle heat production rate is $H_{m_0} = 3.8 \times 10^{-12}$ W kg $^{-1}$ (case 1 in Figure 4). The purple bar in Figure 4b indicates a range of recent CMB heat flow estimates for Earth [Lay et al., 2008]. (d) Evolution of Φ for three models that reproduce Earth’s present-day inner core radius for H_{m_0} and T_{CMB}^{init} values as indicated by the corresponding points labeled (1–3) in Figure 4.

energy release contribute to the entropy production in the core, which causes an abrupt increase in Φ (Figure 5b) and a stronger dynamo. As the core continues to solidify, Φ gradually decreases due to the progressive thinning of the fluid iron layer. Finally, dynamo operation ceases at ~ 8.2 Gyr when core solidification is complete. The onset of inner core formation coincides with a change in the Q_{CMB} slope from negative to nearly flat (Figure 5b, ~ 4.1 Gyr). This is due to (1) the generation of latent heat and gravitational potential energy, which partly replenishes heat carried from the core and maintains high core temperatures, and (2) cooling of the mantle due to decreasing internal heat production, which acts to enhance Q_{CMB} .

[31] We calculated the sensitivity of dynamo evolution to H_{m_0} and T_{CMB}^{init} using three combinations that reproduce Earth’s present-day inner core radius (values as specified in Figure 4). A progressive decrease of T_{CMB}^{init} by 500 K lowers the CMB heat flow, which is reflected in a corresponding decrease in Φ and a delay in the onset time of dynamo operation (Figures 4 and 5d, labels 1–3). Among the models that reproduce Earth’s present-day inner core radius, only those with $T_{CMB}^{init} \gtrsim 5000$ K correspond with an early nonmagnetic epoch < 1 Gyr (label 1 in Figures 4 and 5d), in agreement with evidence for Earth’s long-lived (> 3.5 Ga) magnetic field [Biggin et al., 2008]. We therefore prefer case 1 and use the corresponding values in subsequent models, unless otherwise mentioned.

3.3. Dynamo Evolution for Different Mantle Convection Regimes

[32] Figure 6 shows the evolution of the dynamo in the five mantle convection scenarios (section 2.4 and Table 3).

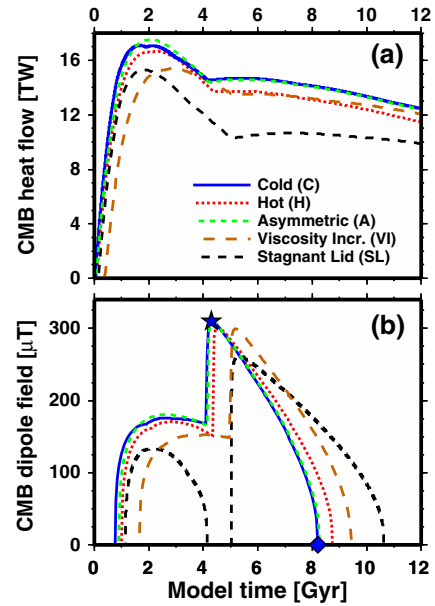

Figure 6. Dynamo evolution for five scenarios of mantle convection (section 2.4 and Table 3). (a) Heat flow at the CMB, Q_{CMB} . Time-dependent mantle heat production is taken into account by rescaling of the steady state Q_{CMB} versus T_{CMB} parameterizations shown in Figure 3a. (b) Magnetic dipole field intensity calculated at the CMB, B_{CMB} . The star and diamond indicate maximum CMB field intensity, B_{CMB}^{max} , and time of dynamo cessation, t_{mag} , for the nominal Earth-like scenario C. The respective symbols correspond with those in Figure 7.

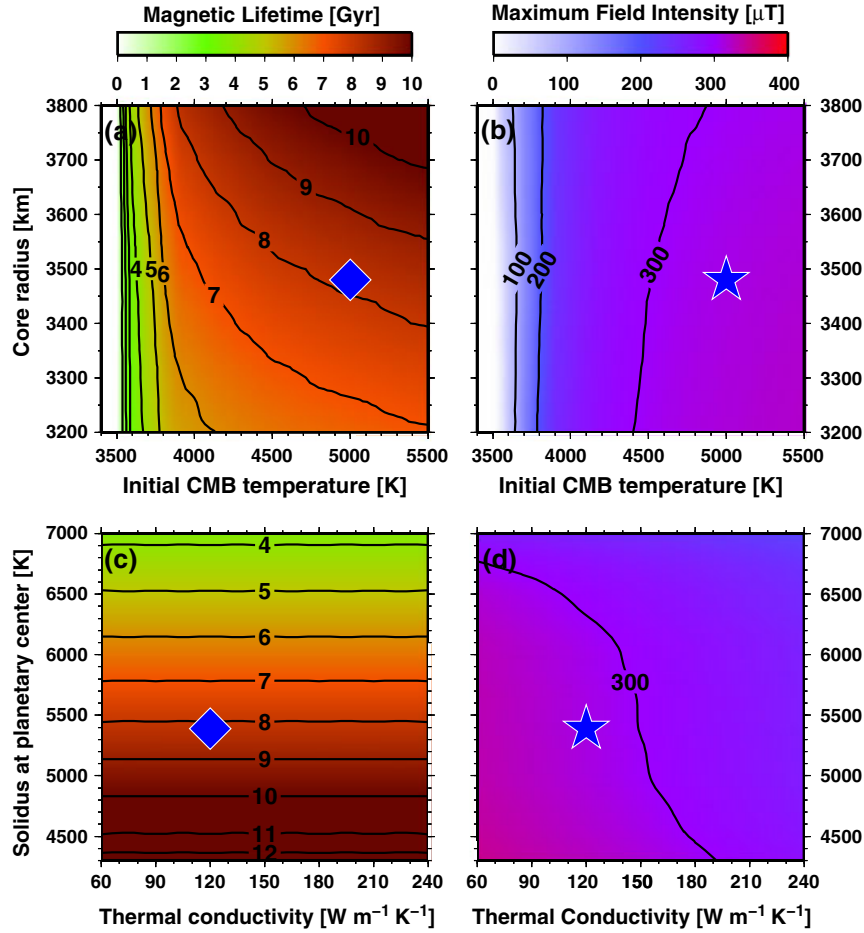

Figure 7. Sensitivity of (a and c) dynamo cessation time t_{mag} , and (b and d) maximum dipole field intensity at the CMB, $B_{\text{CMB}}^{\text{max}}$, as a function of (a and b) initial CMB temperature $T_{\text{CMB}}^{\text{init}}$ and core radius r_{CMB} , and (c and d) core heat capacity k_c and solidus temperature at the planet’s center $T_{\text{sol}}^{\text{cen}}$. Stars and diamonds respectively indicate $B_{\text{CMB}}^{\text{max}}$ and t_{mag} for reference scenario C (Table 3) and correspond with the symbols in Figure 6b.

Throughout most of the evolution, the CMB heat flows for scenarios with plate tectonics or diffuse surface deformation (C, H, A, and VI) are larger by $\sim 2\text{--}4$ TW than for the stagnant lid scenario SL (Figure 6a), a consequence of the Q_{CMB} versus T_{CMB} systematics (Figure 3). The impact of these contrasting heat flows on dynamo evolution is shown in Figure 6b. For scenarios with active surface recycling (C, H, A, and VI), dynamo operation starts at $\sim 0.8\text{--}1.6$ Gyr and continues until core freeze-out ($\sim 8.2\text{--}9.5$ Gyr). For the stagnant lid scenario SL, an early dynamo ceases at ~ 4.1 Gyr because of the low CMB heat flow and corresponding low entropy production in the core. After a magnetic quiet period ($\sim 4.1\text{--}5.0$ Gyr), the dynamo can restart due to inner core formation and continues until ~ 10.6 Gyr, i.e., longer than for all other scenarios that we investigated. The longevity of this second-stage dynamo is due to late freeze-out in a slowly cooling single-plate planet with relatively low CMB heat flow. Unlike the other scenarios, thermal stratification can occur during a substantial part of the evolution of this core ($t_{\text{strat}}=4.4$ Gyr, Table 3). The CMB dipole field strengths B_{CMB} are of similar magnitude in the five different scenarios due to the weak dependence of B_{CMB} on Φ (equation (1)), and this is reflected in the limited

variation in the maximum field intensities in these scenarios ($B_{\text{CMB}}^{\text{max}}=260\text{--}310$ μT , Table 3).

3.4. Sensitivity of Dynamo Evolution to Core Properties

[33] We investigated the sensitivity of dynamo evolution to core radius r_{CMB} , initial temperature $T_{\text{CMB}}^{\text{init}}$, material properties (solidus T_{sol} , and thermal conductivity k_c) in the nominal Earth-like scenario. Figures 7a and 7b show that hotter and bigger cores prolong dynamo operation. Planets with $T_{\text{CMB}}^{\text{init}} \lesssim 3500$ K are nonmagnetic because they (unrealistically) start with and retain a solid core. A progressive increase in $T_{\text{CMB}}^{\text{init}}$ causes a subsequently smaller increase of dynamo cessation times (Figure 7a) because hotter cores lose their heat more efficiently (Figure 3a).

[34] Recent first principle computations of liquid iron mixtures [De Koker *et al.*, 2012; Pozzo *et al.*, 2012] suggest a core thermal core conductivity 2–3 times higher than previous estimates that relied on extrapolations, e.g., Stacey and Anderson [2001]. Our results show that dynamo cessation times t_{mag} are insensitive to k_c in the range $60\text{--}240$ $\text{W m}^{-1} \text{K}^{-1}$ (Figures 7c and 7d). An increase in k_c increases the entropy term related to heat conduction E_K , and this weakens the dynamo (lowers Φ , equation (2)). For

$k_c \gtrsim 160 \text{ W m}^{-1} \text{ K}^{-1}$, the dynamo collapses prior to inner core formation, although this does not affect the cessation times t_{mag} (section 2.2). Dynamo cessation after inner core formation requires even higher k_c ($\gtrsim 500 \text{ W m}^{-1} \text{ K}^{-1}$, outside the range shown in Figure 7c) to offset the latent heat and gravitational energy release contributions. Dynamo operation is insensitive to k_c after inner core formation and for $k_c \lesssim 500 \text{ W m}^{-1} \text{ K}^{-1}$ because of the following: (1) The time of core freeze-out is controlled by Q_{CMB} , which depends on the convective vigor of the mantle but is independent of k_c . (2) The entropy sink term E_K reduces to zero, and this removes the dependence of Φ on k_c (Table 2). These k_c limits are derived using a central solidus $T_{\text{sol}}^{\text{cen}}=5391 \text{ K}$. Dynamo lifetimes decrease for progressively larger T_{sol} (Figures 7c and 7d) because planetary cores solidify at higher temperatures, i.e., generally earlier in the planet’s history.

[35] Peak field intensities are only weakly sensitive to core properties (r_{CMB} , $T_{\text{CMB}}^{\text{init}}$, $T_{\text{sol}}^{\text{cen}}$, k_c) because maximum intensities occur at inner core formation (Figures 5c and 6c) which occurs at a specific temperature regardless of the onset time and because $B_{\text{CMB}} \sim \Phi^{1/3}$ (equation (1)). Intensities decrease sharply, however, when dynamo lifetimes reduce to zero, i.e., for low initial core temperatures ($T_{\text{CMB}}^{\text{init}} \lesssim 3500 \text{ K}$) and high solidus ($T_{\text{sol}}^{\text{cen}} \gtrsim 8400$, Figures 7b and 7d, solidus limit out of the range shown).

4. Discussion

4.1. Comparison With Earth and Venus

[36] Our nominal Earth-like scenario successfully reproduces evidence for a geodynamo that has operated since at least 3.5 Ga [Biggin et al., 2008], and Earth’s present-day inner core radius of 1220 km. The corresponding present-day CMB temperature of 3875 K in our models is compatible with experimental and computational estimates for iron alloys of 3700–4300 K [e.g., Boehler, 2000] and estimates of 3600–4200 K based on seismologically inferred deep mantle structures combined with calculated elastic properties of lower mantle minerals [Lay et al., 2006; Van der Hilst et al., 2007; Kawai and Tsuchiya, 2009]. These constraints restrict the evolution of core energetics, which critically depends on the CMB heat flow. In our preferred scenario, the CMB heat flow is $\sim 15 \text{ TW}$ at $t=4.5 \text{ Gyr}$, consistent with recent estimates of the present-day CMB heat flow (5–15 TW) [Lay et al., 2008]. The CMB heat flow varies between ~ 14 and 17 TW , except for the first $\sim 1 \text{ Gyr}$ when strong mantle heat production impedes core cooling. Our calculations do not require a source of radiogenic heat in the core to match Earth’s long-lived dynamo.

[37] A relatively young inner core ($\sim 500 \text{ Ma}$) and a maximum rate of entropy production associated with ohmic dissipation before and after inner core formation of respectively $\Phi \sim 100 \text{ MW K}^{-1}$ and $\sim 1000 \text{ MW K}^{-1}$ are consistent with other core evolution studies with comparable CMB heat flow values [Labrosse, 2003; Nimmo, 2007]. Previous studies have computed older cores ($\sim 1 \text{ Ga}$), likely because of a lower $Q_{\text{CMB}} \sim 10 \text{ TW}$ [Labrosse, 2003; Breuer et al., 2010; Gaidos et al., 2010]. We prefer relatively high values that prevent the formation of a stably stratified layer in the liquid core (requiring $Q_{\text{CMB}} > Q_K \sim 11\text{--}14 \text{ TW}$, Figure 5b) which, for Earth, is absent or thin ($\lesssim 100 \text{ km}$) [Gubbins, 2007].

[38] In this light, additional mechanisms that can modulate Earth’s CMB heat flow are important. Enhanced CMB heat flow is possible from the decay of ^{40}K in Earth’s core and destabilization of the mantle bottom boundary layer due to a viscosity reduction within deep mantle post-perovskite regions [Nakagawa and Tackley, 2011]. It is possible that Earth’s viscosity increase with depth is larger (factor of ~ 1000) [Mitrova and Forte, 2004; Steinberger and Calderwood, 2005] than employed in our models. Our results show that an increase of the pressure dependence reduces convective overturn in the deep mantle, which lowers the CMB heat flow and weakens the dynamo (cf. models C and VI, Figure 6), consistent with parameterized convection models [Tachiami et al., 2011]. Dynamo operation may be viable for planets with strong pressure-dependence, however, because of sustained convective heat loss due to feedback between viscosity, temperature, and internal heating [Tozer, 1965] (Tackley et al., submitted manuscript, 2013). Possible mechanisms that can decrease the CMB heat flow include a reduced radiative conductivity due to high-pressure transitions from high-spin to low-spin in iron atoms [Badro et al., 2004; Goncharov et al., 2006], thermal insulation due to a compositionally dense layer in the deep mantle [Nakagawa and Tackley, 2004, 2010], and reduced convective heat transport due to a decrease of the thermal expansivity with pressure [Chopelas and Boehler, 1992].

[39] It has been widely debated why a dynamo is absent on Venus, which has a similar size and interior structure as Earth but lacks plate tectonics and has a higher surface temperature. Our stagnant lid model results raise the possibility that a dynamo is currently inactive in Venus because of a low CMB heat flow in the absence of a crystallizing inner core. If true, then a dynamo may restart after the onset of core freezing which enhances the entropy production. This scenario is consistent with previous calculations of Stevenson et al. [1983] and would not require additional mechanisms, such as reduced mantle convection due to dehydration stiffening [Nimmo and McKenzie, 1996; Nimmo, 2002; Gaidos et al., 2010]. Indeed, the influence of an intrinsic viscosity increase may be limited by strong viscosity-temperature feedback [Tozer, 1965].

4.2. Uncertainties and Model Approximations

[40] Several uncertainties and model approximations temper strong statements about dynamo operation in rocky planets. Our viscosity parameterization underestimates the temperature dependence of viscosity of mantle silicates compared to laboratory experiments. Planetary mantles with a stronger temperature dependence likely experience a smaller temperature decrease with time because thermal convection tends to be more self-regulating [Tozer, 1965]. If this causes a smaller temperature difference with the core, then a lower CMB heat flow is expected to weaken dynamo operation. On the other hand, the bottom thermal boundary layer would have a lower viscosity, which locally enhances the mobility of upwellings, and this could increase the CMB heat flow and produce a stronger but shorter-lived dynamo. For planets with immobile surfaces, Li and Kiefer [2007] showed that a stronger temperature dependence results in a thicker upper boundary layer, and this reduces the surface heat flow and increases mantle temperatures, which reduces

the CMB heat flow. A reduced CMB heat flow likely delays inner core formation and hampers dynamo operation until an inner core forms, and this strengthens our explanation for a present-day nonmagnetic Venus.

[41] In rescaling the CMB heat flow to account for time-dependent mantle heating, we have neglected secular cooling of the mantle. Secular mantle cooling would contribute to the energy balance in a similar way as the radiogenic mantle heat production. We may therefore overestimate the CMB heat flow and overestimate dynamo intensities although, for Earth, secular cooling is likely ~ 4 times smaller than internal heating [Turcotte and Schubert, 2002]. However, a larger early CMB heat flow would develop if the early core was superheated relative to the mantle during an out-of-equilibrium thermal state immediately following core-mantle differentiation [Stevenson, 1990]. Also, magmatism, while not included in our models, can enhance the CMB heat flow by cooling the mantle, and this may be particularly important during Earth's early hot stages [Nakagawa and Tackley, 2012] and would promote early dynamo operation. To avoid the formation of an unrealistically large inner core may require a superheated core or other compensatory heat source.

[42] Several processes are not considered in our models for Earth-sized planets but may drive or modulate dynamos of solar system bodies of different size and structure. Mantles much thinner than Earth's allow for efficient core cooling and the growth of an inner core that promotes a chemically driven dynamo, as has been proposed for present-day Mercury [Stevenson *et al.*, 1983]. In contrast, a relatively thick mantle and small core may hamper dynamo operation; this has been proposed to explain the absence of a long-lived dynamo on the Moon [Runcorn *et al.*, 1975]. Although Mars is less massive than Venus, early dynamo cessation due to insufficient CMB heat flow is also a possibility, perhaps triggered by a transition from active tectonics to stagnant lid convection [Nimmo and Stevenson, 2000]. Giant impacts can amplify or generate magnetic fields, which may have contributed to the Moon's paleomagnetic field [Hood and Vickery, 1984]. Mechanical stirring arising from mantle-core differential motion is another possibility for dynamo operation on the early Moon and large asteroids [Dwyer *et al.*, 2011]. Stable stratification in the outer region of a liquid core, with a dynamo operating only at depth, can buffer a magnetic field, and this may cause the weak field of Mercury [Christensen, 2006]. A chemically driven dynamo powered through rise or fall of (sulfur-rich) iron snow has been suggested for Ganymede [Bland *et al.*, 2008; Hauck *et al.*, 2006].

[43] First-principle computations of liquid iron mixtures [De Koker *et al.*, 2012; Pozzo *et al.*, 2012] suggest a thermal conductivity that is 2–3 times higher than previously derived values from extrapolations ($k_c \sim 60 \text{ W}^{-1} \text{ m}^{-1}$) [e.g., Stacey and Anderson, 2001]. We performed the nominal Earth-like scenario at $k_c = 120 \text{ W}^{-1} \text{ m}^{-1} \text{ K}^{-1}$. We demonstrated that in the 60–240 $\text{W m}^{-1} \text{ K}^{-1}$ range, k_c has no influence on the timing of dynamo cessation due to core freeze-out. However, $k_c \gtrsim 160 \text{ W m}^{-1} \text{ K}^{-1}$ may prevent dynamo operation before inner core formation, which would contradict evidence for a terrestrial magnetic field since at least ~ 3.5 Ga. For our stagnant lid scenario SL, lower k_c would likely shorten the magnetic quiet period. This highlights the importance of at

least establishing upper limits to the thermal conductivity under core conditions.

4.3. Implications for Exoplanets

[44] Our results suggest that Earth-mass rocky exoplanets with active surface deformation (plate tectonics or diffuse surface deformation) can have qualitatively similar dynamo evolutions and operate for ~ 8.2 – 9.5 billions of years, irrespective of surface temperature (273–759 K). A longer-lived (~ 10.5 Gyr) dynamo is possible with stagnant lid convection, due to the lower CMB heat flow. These dynamo lifetimes raise the question whether the interior dynamics of Earth-mass rocky exoplanets can be inferred by combining magnetic field detections and planet age estimates. The ages of stars (and their planets) can be inferred with a precision that would be sufficient for identifying planets in different phases of core thermal evolution, i.e., ~ 1 – 2 Gyr [Mamajek and Hillenbrand, 2008]. Unfortunately, our results suggest that uncertainties in planetary rock properties make a distinction between planets with active surface recycling and stagnant lid planets extremely challenging. We demonstrated that characterization of exoplanet interior dynamics requires well-determined radius, initial temperature, solidus, and thermal conductivity of the core (Figure 7). In particular, the strong sensitivity to the solidus emphasizes the need for constraining the equation of state of iron under core pressures and temperatures.

[45] What dynamo behavior can be expected for planets more massive than Earth? For rocky planets larger than ~ 2 Earth masses, it takes >4.5 Gyr to form an inner core and dynamo action before that time must be maintained by thermal convection [Gaidos *et al.*, 2010; Driscoll and Olson, 2011]. The pressure-dependence of mantle viscosity is still debated [Stamenković *et al.*, 2011; Karato, 2011] but has important implications for mantle dynamics. Our results demonstrate that a viscosity increase of 1 order of magnitude across the mantle depth will hamper deep mantle convection and attenuate but not stop dynamo operation. Because terrestrial planets more massive than Earth have higher mantle pressures, their material properties probably depart more radically from terrestrial values. This makes it even more challenging to reliably predict dynamo lifetimes for massive Super-Earths.

4.4. Detection of Magnetic Fields on Exoplanets?

[46] Charged particle belts in the magnetospheres of Earth and the giant planets emit electron cyclotron emission at MHz frequencies. Magnetodynamo-hosting planets around other stars could presumably emit at similar frequencies and power levels [Hess and Zarka, 2011]. Searches for Jupiter-like emission from giant exoplanets have been undertaken [Bastian *et al.*, 2000; Lazio and Farrell, 2007; George and Stevens, 2007; Farrell *et al.*, 2004; Lazio *et al.*, 2010a, 2010b; Lecavelier Des Etangs *et al.*, 2011]. However, predicted frequencies for Earth-like dynamos are below the 10 MHz cutoff of Earth's ionosphere. Moreover, an empirical relation between emitted power and magnetic moment [Zarka, 2007] predicts that power emission is well below the detection threshold of even the most sensitive radio telescope (Low-Frequency Array) [Farrell *et al.*, 2004; Driscoll and Olson, 2011; Lazio *et al.*, 2010b]. Detection would require a fortuitous combination of increased

stellar activity [Grießmeier *et al.*, 2005], beamed emission in the direction of Earth, or intensification by a stellar flare [Driscoll and Olson, 2011]. Detection might also be possible with radio telescopes in space, which would not suffer from the low-frequency ionospheric cutoff.

[47] The magnetic field of a planet on a close-in orbit can interact with the field of its host star; periodic chromospheric emission from the host stars of some “hot Jupiters” could be the result of connectivity between the fields of the planet and the star [Shkolnik *et al.*, 2008; Lanza, 2011]. Other observable phenomena are associated with a planetary dynamo: A magnetic field could alter the circulation and temperature distribution of a partially ionized upper atmosphere of a “hot” Earth [Castan and Menou, 2011], perhaps changing the pattern of reflected or emitted light, although these effects have yet to be explored. A magnetized “tail” of gas escaping from a planet could polarize transmitted light [Tachinami *et al.*, 2011] or a bowshock could produce an asymmetry or variability in the in the primary occultation signal of a transiting planet [Vidotto *et al.*, 2011a, 2011b].

[48] The persistence of an atmosphere on a low-mass planet close to its host star is possible indirect evidence for a planetary dynamo, because a strong magnetic field protects the planet’s atmosphere against erosion by a stellar wind and coronal mass ejections. The dense plasma environment close to the host star can remove hundreds of bars equivalent atmosphere from an unmagnetized Earth-size planet over several Gyr [Khodachenko *et al.*, 2007; Lammer *et al.*, 2007]. Any primary atmosphere dominated by H₂ and He would be rapidly removed unless protected by a magnetic field. The presence of an atmosphere on a transiting planet can be detected by absorption features in spectra obtained during a transit [Charbonneau *et al.*, 2002; Bean *et al.*, 2010] or by its redistribution of heat [Gaidos and Williams, 2004; Knutson *et al.*, 2007]. Limitations to using planetary atmospheres to infer a magnetodynamo are that planets can conceivably accrete without atmospheres [Raymond and Meadows, 2007; Lissauer, 2007] or may have lost their atmospheres early in their evolution due to increased stellar activity and before any dynamo started. We calculated an initial nonmagnetic period of ~1–1.5 Gyr for all our model scenarios (Table 3) due to high rates of radiogenic mantle heating, which leaves all such planets vulnerable to loss of an atmosphere. Secondary atmospheres of volcanic CO₂, H₂O, and N₂ may form but could also be removed by thermal escape and stellar wind erosion [Khodachenko *et al.*, 2007; Tian, 2009]. These possible complications will challenge attempts to infer the operation of a dynamo through the presence or absence of atmospheres on exoplanets.
